ABSTRACT

Aims. We trace the interaction processes of galaxies at intermediate redshift by measuring the irregularity of their gas kinematics, and investigate these irregularities as a function of the environment (cluster versus field) and of morphological type (spiral versus irregular).

Methods. To quantify irregularities in the gas kinematics, we use three indicators: the standard deviation of the kinematic position angle (σ_{PA}), the mean deviation of the line of sight velocity profile from the cosine form which is measured using high order Fourier terms ($k_{3,5}/k_1$) and the average misalignment between the kinematical and photometric major axes ($\Delta\phi$). These indicators are then examined together with some photometric and structural parameters such as the disk scale length, rest-frame colors, asymmetry, concentration, Gini index and M_{20} . Our sample consists of 92 distant galaxies. 16 cluster ($z \sim 0.3$ and $z \sim 0.5$) and 29 field galaxies ($0.10 \leq z \leq 0.91$, mean $z=0.44$) of these have velocity fields with sufficient signal to be analyzed. To compare our sample with the local universe, we analyze a sample from the SINGS survey.

Results. We find that the fraction of galaxies that have irregular gas kinematics is remarkably similar in galaxy clusters and in the field (according to $\sigma_{PA} \approx 10\%$, $k_{3,5}/k_1 \approx 30\%$, $\Delta\phi \approx 70\%$). The distribution of the field and cluster galaxies in (ir)regularity parameters space is also similar. We do not find a dependence of the irregularities in gas kinematics on morphological type. We find that two different indicators of star formation correlate with irregularity in the gas kinematics. This relation is consistent with theory and both correlations are found with the $\Delta\phi$ parameter, which shows that $\Delta\phi$ is a good indicator of interaction processes. We also find larger misalignments between the stellar disk and the rotation plane of the gas for cluster members with less massive stellar disks.

Conclusions. Gas velocity fields of spiral galaxies in the field are more irregular at intermediate redshifts than in the local universe, which indicates that these galaxies are probably still in the process of building their disks via mechanisms such as accretion and mergers. We find less irregular gas kinematics at intermediate z than that has been found at $z \sim 2$.

Key words. galaxies: evolution – galaxies: kinematics and dynamics – galaxies: clusters: individual: MS 0451.6–0305, MS 2137.3–2353, MS 1008.1–1224, Cl 0412–65 – galaxies: spiral

1. Introduction

Galaxy clusters are important laboratories for understanding the origin of different morphological types of galaxies. The main reason for that is the relation between local galaxy density and morphological type (Dressler 1980). For nearby rich clusters, the spiral galaxy fraction decreases from 80% in the field to 60% in the cluster outskirts and to virtually zero in the core region. This relation is redshift dependent and while the fraction of elliptical galaxies ($\sim 15\%$, Vogt et al. 2004) does not change with redshift, the S0 fraction increases with decreasing redshift and the spiral fraction, on the contrary, decreases (Couch

et al. 1998). The fraction of spirals with no current star formation activity is significantly larger in clusters than in the field (van den Bergh 1976; Poggianti et al. 1999; Couch et al. 2001; Goto et al. 2003; Verdugo et al. 2008; Sikkema 2009). Also, distant clusters have a larger fraction of star forming galaxies compared to nearby clusters (Butcher & Oemler 1978, 1984; Ellingson et al. 2001; Kodama & Bower 2001). It is well established with these observational studies that spiral galaxies have been transformed into S0s mostly in denser regions of the universe. Then the question is what are the physical processes that are responsible for this morphological transformation. Several mechanisms have been proposed such as gas stripping mechanisms: ram pressure stripping (Gunn & Gott 1972; Quilis et al. 2000; Kronberger et al. 2008; Kapferer et al. 2008, 2009), viscous stripping (Nulsen 1982) and thermal evaporation (Cowie & Songaila 1977); tidal forces due to the cumulative effect of many

[★] Based on observations collected at the European Southern Observatory (ESO), Cerro Paranal, Chile (ESO Nos. 74.B–0592 & 75.B–0187) and observations of the Hubble Space Telescope (HST No 10635).

weak encounters: harassment (Richstone 1976; Moore et al. 1998); removal of the outer gaseous halos by the hydrodynamic interaction with the ICM plus the global tidal field of the cluster: starvation (Larson et al. 1980); mergers and strong galaxy-galaxy interactions which are efficient when relative velocities are low, and therefore they mostly occur in galaxy groups or in the outskirts of clusters (Makino & Hut 1997). It is known that cluster galaxies lose gas because of their interactions with the intra-cluster medium (ICM) and as a result, their star formation gets switched off. Local studies show that cluster galaxies are deficient in neutral hydrogen compared to their field counterparts and that becomes significant within the Abell radius (Davies & Lewis 1973; Giovanelli & Haynes 1985; Gavazzi 1987, 1989; Solanes et al. 2001). The HI distribution of these galaxies frequently shows asymmetries and displacement from the optical disk as well (Gavazzi 1989; Cayatte et al. 1994; Bravo-Alfaro et al. 2000; Vogt et al. 2004). It was proposed that passive spiral galaxies in clusters might be the intermediate phase before becoming an S0 (van den Bergh 1976). Later on, it was argued that S0's can not be formed by removing gas from disks of spirals via mechanisms such as ram pressure stripping, since S0's have systematically larger bulge sizes and B/D ratios compared to spiral galaxies in all density regimes (Burstein 1979; Dressler 1980; Gisler 1980 but see also Aragón-Salamanca 2008). Tidal interactions (e.g. harassment) on the other hand are expected to trigger gas accretion into the circumnuclear regions (Moore et al. 1996) and therefore increase the bulge size and B/D ratio. Therefore S0's might have formed via minor mergers, harassment or a combination of the two (Dressler & Sandage 1983; Neistein et al. 1999; Aguerri et al. 2001; Hinz et al. 2003).

All these discussions are pointing out that studying stellar populations and morphologies of cluster galaxies is crucial in understanding the interaction processes. What about their kinematics? In the Virgo cluster, for example, half of 89 spiral galaxies that were observed by Rubin et al. (1999) turned out to have disturbed gas kinematics. Mergers and tidal processes such as harassment are capable of causing disturbances also in stellar velocity fields (Moore et al. 1999; Mihos 2004). ICM-related processes on the other hand, even ram-pressure stripping are insufficient to be able to affect stellar kinematics of spiral galaxies (Quilis et al. 2000). Some attempts have been made to evaluate the effectiveness of the interaction processes as a function of location in the galaxy cluster. Dale et al. (2001) measured TF residuals for 510 cluster spirals and concluded that they do not show a dependence on distance from the cluster center. Moran et al. (2007b) constructed the TFR in both K_S and V bands for 40 cluster, 37 field spirals at intermediate redshift and found that the cluster TFR exhibits significantly larger scatter than the field relation in both bands and the residuals do not show a clear trend with R/R_{vir} . They found that the TFR residuals do not correlate with the star formation rate and dust content. They also checked whether central surface mass density of galaxies, which can be used to probe the action of harassment, shows a trend as a function of radius. They found that it shows a break at approximately $1R_{vir}$, outside of which spirals exhibit nearly uniformly low central density values. They argue that a combination of merging in the cluster outskirts with harassment in the intermediate and inner cluster regions might explain both the TF scatter and the radial trend in density which persist up to $2R_{vir}$.

As discussed above, galaxy evolution in clusters is rather complex, since there are several interaction mechanisms involved. To understand the nature of these mechanisms, it is important to examine together morphological and kinematical properties of cluster galaxies. In this series of papers we make

use of both gas velocity fields and high resolution images of galaxies in four intermediate-redshift clusters and their field to do that. Most studies in the literature rely on long-slit data for identifying kinematical disturbances. Using a velocity map enables us to have a more accurate measure of the kinematical (ir)regularity. A velocity field can be decomposed into velocity, position angle and inclination of circular orbits at each radius (see Krajnović et al. 2006). The deviation of the kinematic major axis (KMA) around its mean value and the misalignment between KMA and the photometric major axes (PMA) both indicate kinematical disturbance. We also make a simple rotating model that has the mean position angle and inclination of the observed velocity map. The residual of the observed and the simple rotating map is fitted with high order Fourier terms and the squared sum of these terms is used as another indicator. We measure these irregularity indicators for both field galaxies and cluster members and compare them with each other to search for the environmental imprint on gas kinematics. We then combine this information with the morphological and photometric properties of these galaxies and investigate whether certain characteristics make galaxies more sensitive to environmental effects. We also use the relations between intrinsic galaxy properties and efficiency of interaction processes, that are known from theory, to investigate which mechanisms are at work on the cluster galaxies in our sample.

We also investigate the evolution of field galaxies by studying their gas kinematics as a function of redshift. We measure the irregularities in their gas kinematics both at intermediate redshifts and in the local universe and compare them with each other. These results are then compared with the studies of spatially resolved gas kinematics at similar or higher redshifts: Shapiro et al. (2008) analyzed gas velocity fields and velocity dispersion maps of 11 galaxies at $z \sim 2$, observed with adaptive optics assisted spectrograph SINFONI, and classified these systems into two categories: merging and non-merging. They found that more than %50 of these galaxies are consistent with a single rotating disk interpretation. With FLAMES at the VLT, Yang et al. (2008) studied 63 intermediate-mass field galaxies at $0.4 < z < 0.75$. Using spatially resolved gas kinematics of these objects, ($2'' \times 3''$ field of view) they find that both velocity fields and velocity dispersion maps of 26% of these galaxies are incompatible with disk rotation.

We described our method and presented the analysis of our MS 0451 sample in Kutdemir et al. (2008, Paper III). Here, we include in our analysis galaxies in three more intermediate redshift clusters and their field. A plan of the paper follows. In Sect. 2, we describe our sample, in Sect. 3 we describe the improvements in our data reduction technique in comparison with Paper III. In Sect. 4, we give the definition of the photometric parameters that are different from the ones we used in Paper III. In Sect. 5, we explain the analysis of the data, In Sect. 6, we discuss our results and compare them with the literature. Sect. 7 summarizes the results and our conclusions.

Throughout this paper, we assume that the Hubble constant, the matter density and the cosmological constant are $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$ respectively (Tonry et al. 2003)

2. Sample

Our sample includes four galaxy clusters which have different properties (Table 1). To be able to compare the galaxies that experience similar environmental conditions, we scale cluster-centric distance by each cluster's virial radius. It is known that

even galaxy clusters at the same redshift can be very different from one another. Two well-studied rich clusters in the local universe, Coma and Virgo are a good example for that. While Coma is dynamically relaxed and spiral poor, Virgo on the contrary is unrelaxed and spiral rich (Poggianti 2006).

Here we give some information about each cluster in our sample: MS 0451 is a massive cluster with very high X-ray luminosity. 28% of its spiral population are passive (Moran et al. 2007a); MS 1008 is a very regular and rich cluster (Lewis et al. 1999; Luppino et al. 1999); MS 2137 is a rich and dynamically relaxed cluster (Jeltema et al. 2005); Cl 0412 (F1557.19TC) is a poor cluster that is not well-studied. Our cluster selection depended on the availability of their HST/WFPC2 imaging when the project started in 1999. See Ziegler et al. 2003, Paper I and Jäger et al. 2004, Paper II for more detailed information about the sample selection.

During the target selection, we gave priority to galaxies from our previous studies both in field and cluster environments that have emission lines that are strong enough for extracting velocities. Further objects were drawn from a catalog provided by the CNOC survey (Ellingson et al. 1998) with either redshift information or measured (g-r) color that matches expectations for spiral templates at $z \approx 0.5$. If there was an unused slitlet in the MXU setup, and no suitable candidate was available, a galaxy was picked at random. For our analysis, we also use a sample from SINGS as a local reference for comparison (see Paper III). SINGS galaxies are a diverse set of local normal galaxies (Kennicutt et al. 2003). Daigle et al. (2006)’s subsample that we use in our analysis consists of galaxies that have star forming regions, so that their H_α kinematics could be extracted. We excluded from our analysis the galaxies in this sample that have luminosities that are very different from the luminosities of our intermediate redshift sample, so that the two samples have comparable stellar masses. In Fig. 1, we compare the H_α luminosities of galaxies in our sample and in the local sample. Since the galaxies in our sample were selected mainly based on the strength of their emission, several of them have larger H_α luminosities, and therefore higher star formation rates than the galaxies of the local sample.

We presented the analysis of our MS 0451 sample in Paper III. We give the basic information about the rest of the sample in Table 2. The first character of a galaxy name indicates the sample (1:MS 0451 ; 2:MS 1008 ; 3:MS 2137 ; 4:Cl 0412). The second character is ‘‘C’’ for cluster members and ‘‘F’’ for field galaxies. The last part of the name assigns a number to each galaxy. We identified galaxies with redshifts between 3σ below and above the cluster redshifts as cluster members. Only for MS 0451, which was analyzed in Paper III, we used the redshift interval defined by Moran et al. (2007b) using the redshift distribution of over 500 objects. That gives an interval which

Fig. 1. Distribution of H_α luminosities of both our galaxies and a local sample from SINGS. The local sample is given in cyan, shaded at -45° , our sample: field galaxies in red (shaded at 45°) and cluster galaxies in light yellow (not shaded).

is $\Delta z = 0.006$ larger on both sides than what the 3σ definition gives. For Cl 0412, Dressler et al. (1999) determined cluster membership using the redshift distribution of 22 galaxies. The redshift interval they define selects the same galaxies as the 3σ criterion to be cluster members.

In the Appendix, we give some information about each galaxy. In case the galaxy has emission lines, we present:

- a– the HST-ACS image of the galaxy in the $F606W = V$ band;
- b– rotation curves of different emission lines (and for some cases based on the absorption lines) extracted along the central slit without correction for inclination and seeing;
- c– position angles of kinematic and photometric axes as a function of radius;
- d– rotation curves extracted along the central slit and the kinematic major axis;
- e– velocity field obtained using the strongest line in the spectrum;
- f– velocity map reconstructed using 6 harmonic terms;
- g– residual of the velocity map and the reconstructed map;
- h– normalized flux map of the line used for constructing the velocity field;
- i– simple rotation map constructed for position angle and ellipticity fixed to their global values;
- j– residual of the velocity map and the simple rotation model;
- k– position angle and flattening as a function of radius;
- l– k_3/k_1 and k_5/k_1 (from the analysis where position angle and ellipticity are fixed to their global values) as a function of radius.

3. Data reduction

Our observations were spread across 5 nights in October and November 2004 for Cl 0412 (seeing $0''.57$ (FWHM)); 7 nights in December 2004 and February 2005 for MS 1008 (seeing $0''.73$); 5 nights between May and July 2005 for MS 2137 (seeing $0''.76$). Each sample was observed using three masks and the integration time of each mask was split into three exposures. Even in cases where all three exposures were taken during the same night, the frames were not perfectly aligned. Therefore we completed the reduction of each frame before combining them.

The spectral data reduction was done in the same way as explained in Paper III, apart from using a different sky subtraction

Table 3. Eye-ball morphological classification of the MS 0451 sample.

| ID | IC1 | IC2 | IC3 | IC4 | IC5 | IC6 | IC7 | IC8 | IC9 | IC10 | IC11 |

method, which improved the results considerably. In Paper III, the sky is modelled in spectra that are interpolated along the X axis for wavelength calibration. Here we use the algorithm described in Kelson (2003) which is based on modelling the sky in the original data frame as a function of the rectified coordinates. Modelling the sky before applying any rectification/rebinning to the data reduces the amount of noise that is introduced to the data during the sky-subtraction process (see also Milvang-Jensen et al. 2008).

To be able to compare the $H\alpha$ emission line fluxes of our sample with the local sample, we applied a rough flux calibration to our data. We used the spectrum of a star that we observed together with our MS 0451 sample for the calibration of all our data since they were observed with the same instrument. The star that we used is U0825_01208341 in the PMM USNO-A2.0 catalogue of Monet et al. (1998). We transformed the B and R magnitudes of the star given in the catalog onto the standard Johnson-Cousins system using the conversions provided by Kidger (2003).

4. Photometry

Environmental effects on how a galaxy evolves depend on its intrinsic properties. For example it is known that harassment is more efficient on low central surface mass density galaxies (Moore et al. 1999). In this context, it is important to test whether the abnormalities that we see in gas kinematics of a galaxy correlate with its photometrical properties. To investigate this issue, we use both VLT/FORS2 and HST/ACS images. We obtained imaging of the MS 1008, MS 2137 and CI 0412 samples in the ACS/F606W filter while we exploited existing imaging of MS 0451 in the ACS/F814W filter from the ST-ECF HST archive. Ground based images were taken in the B, V, R and I filters for the whole sample. The FORS2 filters B, V and I are close approximations to the Johnson-Cousins (Bessell 1990) photometric system while the R filter is a special filter for FORS2 that is similar to the Cousins R¹.

Surface photometry analysis, magnitude measurements, extinction and k-correction were done in the same manner as explained in Paper III. We have not applied an internal dust (inclination) correction. Galactic extinction and k-corrected M_B magnitudes, rest-frame B - V, V - R and R - I colors of the galaxies in our sample are given in Table B.1.

We use slightly different definitions for asymmetry and concentration parameters than in Paper III. Here we give the new definitions that are based on Abraham et al. (1996) and Conselice et al. (2000). The concentration is the ratio of the flux within G_1 , the area inside the 1σ isophote of the sky level and G_2 , the region which has the same axis-ratio as G_1 , but has a major-axis size that is 0.3 times the major-axis size of G_1 :

$$C = \frac{\sum_{i,j \in G_2} I_{ij}}{\sum_{k,l \in G_1} I_{kl}} \quad (1)$$

¹ The FORS2 filter curves are given at <http://www.eso.org/instruments/fors/inst/Filters/curves.html>

The asymmetry parameter A is the normalized residual of a galaxy image and its 180 degrees rotated counterpart. It is calculated within the 1σ isophote of the galaxy (Eq. (2)). The central pixel for the asymmetry measurement is determined by shifting the galaxy on a 50×50 grid and finding the minimum A. The asymmetry of a blank area was measured in the same way in the vicinity of the object to correct for the contribution of the background noise.

$$A = \left(\frac{\sum_{i,j} |I(i,j) - I_{180}(i,j)|}{\sum_{i,j} |I(i,j)|} \right) - \left(\frac{\sum_{k,l} |B(k,l) - B_{180}(k,l)|}{\sum_{i,j} |I(i,j)|} \right). \quad (2)$$

We measure two additional parameters that we did not use in Paper III: the Gini coefficient and the M_{20} index (Abraham et al. 2003; Lotz et al. 2004). The Gini coefficient gives the concentration of a light profile, similar to C, but it is insensitive to the definition of the central pixel (Eq. (3)).

$$G = \left(\frac{1}{|\bar{f}|n(n-1)} \right) \sum_{i=1}^n (2i-n-1)|f_i|, \quad (3)$$

where $|f_i|$ are the absolute flux values of a galaxy's constituent pixels sorted in increasing order, $|\bar{f}|$ is their mean value and n is the number of pixels.

The M_{20} index is based on the total second-order moment M_{TOT} , which is the flux in each pixel f_i multiplied by its squared distance to the galaxy center, summed over all pixels of the galaxy (Eq. (4)).

$$M_{TOT} = \sum_{i=1}^n M_i = \sum_{i=1}^n f_i((x_i - x_c)^2 + (y_i - y_c)^2). \quad (4)$$

x_c and y_c are the coordinates of the galaxy center which are determined in a way to minimize M_{TOT} . M_{20} is the normalized second order moment of the brightest 20% of the galaxy's flux (Eq. (5)). To compute M_{20} , the pixels are ordered such that i increases with decreasing flux, and M_i is summed over the brightest pixels until the integrated value reaches 20% of the total galaxy flux:

$$M_{20} = \log\left(\frac{\sum_i M_i}{M_{tot}}\right) \text{ while } \sum_i f_i < 0.2 f_{tot}. \quad (5)$$

M_{20} traces the spatial distribution of bright features such as star forming regions.

We present the asymmetry, concentration, Gini and M_{20} parameters of our galaxies in Table B.1 in the Appendix. The same parameters for the SINGS galaxies are given in Table 4. The rest-frame wavelength of the ACS images of our sample corresponds to the B band, therefore we used blue KPNO, CTIO, Palomar and Isaac Newton images of the SINGS galaxies for the measurements. These images are convolved with a point spread function and then rebinned to have the same seeing and pixel size in kpc as the HST images of our sample at the mean redshift of our clusters ($z = 0.4$). The asymmetry and concentration parameters can be used for morphological classification. We present

Column (1): object ID; Col. (2): asymmetry index; Col. (3): concentration index; Col. (4): Gini coefficient; Col. (5): M_{20} index.

We could not obtain reliable measurements of the photometric parameters of NGC3621, NGC4236, NGC2976 and NGC7331 because of the large number of stars and artifacts on the images. Therefore they are not used in our analysis.

Fig. 2. Distribution of galaxies in our sample and a local sample from SINGS on the $A - C$ plane. Their morphological types, that are determined by our eye-ball classification (Table 2, Col.6.), are indicated with different symbols as shown at the bottom of the graph. The dash-dotted purple lines are the selection limits separating different morphological types determined by Menanteau et al. (2006). The borders that are adjusted by minimizing the amount of contamination from different types in each region are shown with black dotted lines.

our galaxies and local galaxies from SINGS on the $A - C$ plane together with our eye-ball classification of their morphologies in Fig. 2. Selection limits which separate different morphological types on the plane as determined by Menanteau et al. (2006) are shown on top of this plot. The borders are then adjusted by minimizing the amount of contamination from different types in each region.

5. Analysis

We analyze the gas kinematics of our whole sample in the way that was described in Paper III, using a sample from SINGS as a local reference for comparison (see Paper III). As stated in the introduction section, we look for indications of disturbance in velocity fields to be able to examine environmental effects.

Fig. 3. SFR versus stellar mass for our sample and the local sample from SINGS. The SFR-stellar mass relation based on $z \sim 1$ galaxies from GOODS Elbaz et al. (2007) and the local relation from Salim et al. (2007) are overplotted for comparison. The stellar masses of the SINGS galaxies are calculated using their M_B and B-V as explained in Bell et al. (2005).

Fig. 4. Specific star formation rate versus rest-frame B-V color for our sample and the local sample from SINGS.

There are three parameters that we use for quantifying these abnormalities:

- a*– the standard deviation of the kinematic position angle (σ_{PA});
- b*– the average misalignment between the photometric and kinematic axes ($\Delta\phi$);
- c*– the mean deviation of the velocity field from a simple rotating disk ($k_{3,5}/k_1$).

The line of sight (LOS) velocity profile of a simple rotating disk is a cosine function (Krajnović et al. 2006). Our last (ir)regularity parameter measures the deviation from the cosine form that can be represented with the third and the fifth order terms of the Fourier series. The exact definition of each of the

(ir)regularity parameters is given in Paper III. Their values for each galaxy are listed in Table 5. Examination of the data shows that in some special cases these measurements have to be excluded from the analysis (explained in Sect. 5.6).

5.1. Star Formation Rates

Here we analyze the star formation properties of the galaxies in our sample. We use the total fluxes of available emission lines in the spectra to measure the star formation rates (SFR). The luminosities are calculated using these fluxes and corrected for extinction following Tully & Fouqué (1985). The inclinations are measured from our HST/ACS imaging (Table B.2). For a comparison between different extinction corrections, we have applied the definitions of Giovanelli et al. (1994) and Tully et al. (1998), which makes a factor of 10% difference at most in SFRs. Tully & Fouqué (1985) better matches the extinction law (Cardelli et al. 1989) for reasonable values of $E(B-V)$. Star formation rates that rely on [OII]3727 or H_α line were calculated applying Kennicutt (1992) and for H_β , case B recombination was assumed, which implies a factor 2.86 difference in comparison with H_α . Note that we have not corrected the H_β luminosities for underlying stellar absorption. For the calculations based on [OIII]5007 we have followed Maschietto et al. (2008) and Teplitz et al. (2000).

In Fig. 3, we plot the SFR versus stellar mass for the galaxies in our sample. A comparison with the relations for $z \sim 1$ and $z \sim 0$ galaxies and the SINGS local sample shows that SF properties of the galaxies in our sample cover a wide range and some galaxies have higher star formation rates than the $z \sim 1$ relation. It should be noted that this relation has a large intrinsic scatter at all redshifts. In Fig. 4 we show specific SFR versus rest-frame B-V which follows the expected trend.

Since we calculated the star formation rates using the integrated flux from three adjacent slits that cover a galaxy, aperture effects are negligible. On the other hand, we are forced to use different emission lines for calculating SFRs due to the different rest-frame wavelength coverage of the spectra from galaxies at different redshifts. The conversions that are used for this purpose are likely to cause some systematic errors (Moustakas et al. 2006). To check for our sample, how successful it would be to use a constant factor for conversion from one emission line flux to the other, we plot the frequency distribution of emission line flux ratios in Fig. 5. This exercise shows that the uncertainty in H_α luminosities (Table 8) that is caused by these differences is about a factor 2.

5.2. Frequency Distribution

In Fig. 6 d, e and f, we show the frequency distribution of each (ir)regularity parameter for the field and cluster galaxies in our sample. The same information for local galaxies is given above each plot for comparison (Fig. 6 a, b and c). Cluster and field galaxies are distributed in a similar manner in the (ir)regularity parameters space. Both cluster and field galaxies populate regions inside and outside the area where regular velocity fields of local galaxies are located. The Kolmogorov-Smirnov (K-S) test of the distributions also confirms that field and cluster populations are not significantly different from one another (see Table 6). Here we discuss the origin of the largest parameter values: The two galaxies that have the largest σ_{PA} values are 1F6 and 4F7. 1F6 has a kinematically decoupled core, therefore it is probably a merger remnant (Paper III, Fig. B.13). 4F7 seems

Fig. 5. Histograms of the emission line flux ratios

to be a merger too. The residual of its velocity field and reconstructed velocity map reveals the existence of a counter-rotating component in the outer part (see Fig.B.49.g and j). There are tidal structures visible on its HST image as well (Fig.B.49.a). The largest $\Delta\phi$ belongs to 3F7 which has a strong bar (Fig.B.39). Although the kinematic and the photometric position angles match quite well in the disk region, the extent of the observed velocity field does not go far outside the bar (see Fig.B.39.a,c,e), therefore this galaxy has a very large $\Delta\phi$ value. $\Delta\phi$ clearly has an important contribution of a bar in case of two other galaxies in our sample: 1F6 and 2C3. So a large $\Delta\phi$ either indicates a misalignment between the stellar disk and the kinematic axis of the gas, or the presence of a bar.

5.3. Correlations Between (Ir)regularity Parameters

To be able to use the (ir)regularity parameters as a tool to distinguish disturbed velocity fields from regular ones, it is necessary to determine a threshold value for each of them. We did that by measuring each parameter for local, regular velocity fields from SINGS (see Paper III, Sect. 4). In Fig. 7, we show how the galaxies in our sample and in the local sample are distributed in the plane of one parameter versus another. Regularity borders that are defined using the local galaxies are indicated on each plot. We find a weak correlation between $k_{3,5}/k_1$ and σ_{PA} (see Table 7) which agrees with what we found in Paper III using only the MS 0451 sample. If we look at the galaxies that have large $k_{3,5}/k_1$ and σ_{PA} parameters, most of them show signs of an additional kinematic component in the residual of the simple rotating model and the original velocity field (residual maps are presented in the Appendix, part (j) of each figure). These galaxies are 1F4, 1F6, 4F7 and 4F8. In all cases, the existence of a secondary component is clear in the residual map. k_5 is sensitive to extra kinematic components and σ_{PA} is sensitive to their misalignment with the main component. Therefore, the outliers of the $k_{3,5}/k_1$ versus σ_{PA} plot mostly consist of velocity fields that have multiple kinematic components. This explains the weak correlation between these two parameters.

5.4. Dependence On the Clustercentric Distance

All cluster members in our sample, except for 4C2, are well inside the virial radius, where both tidal processes and ICM-related mechanisms are effective. In Fig. 8, we show the distance of each galaxy from the cluster center in projection (in virial radii) and plot that against (ir)regularity parameters. There are quite a few galaxies within half a virial radius from the center, that are below the irregularity threshold of $k_{3,5}/k_1$ and σ_{PA} . $69 \pm 11\%$ of the cluster galaxies are regular according to both of these parameters while most of them have large $\Delta\phi$ values. The fraction of galax-

ies within $1 R_{vir}$ that have regular gas kinematics according to all the three criteria is $13 \pm 8\%$.

5.5. Correlations With Photometric Parameters

We determine the correlations between the (ir)regularity parameters and some morphological/photometric parameters (Table 7). We find an anti-correlation between $\Delta\phi$ and the rest frame B-V color (Fig. 9) which will be discussed in the following section. The cases for which the correlation coefficient is 0.5 or above, and where the trend is difficult to see, are given in the Appendix, Fig. A.1. Galaxies from the local sample are shown on these plots for comparison. They are not used in correlation measurements, except for the ones with redshift. Apart from the Gini index, M_{20} , photometric asymmetry and concentration parameters that are defined in Sect. 4, the methods we use for measuring the morphological/photometric parameters are explained in Paper III. H_α luminosities are listed in Table 8. In case the H_α line was outside the observed wavelength interval, we converted the fluxes of available emission lines to H_α flux from the SFRs that are measured as explained in Sect. 5.1 using the conversion factor that is provided by Kennicutt (1992). Photometric and morphological parameters of the galaxies in our sample are given in Table B.1 and Table B.2 respectively (see Paper III, Table C.2 for the morphological parameters of the MS 0451 sample.). The (ir)regularity parameters of the local sample galaxies are given in Paper III, Table 3. Their photometric parameters are given here, in Table 4.

In Sect. 4, we determined the morphological type of the galaxies by our eye-ball classification (Table 2 & Table 3). Here we check how the (ir)regularity parameter values of different morphological types are distributed (Fig. 10) and find that irregularities in gas kinematics of spiral and irregular galaxies are very similar (see Table 9 for the K-S test results).

To focus on the effects of the interactions that take place only in clusters, we now restrict ourselves to our cluster sample, where most galaxies are within half a virial radius from the cluster center. In this region, mergers are rare, while harassment and ICM related mechanisms such as ram pressure stripping are expected to be effective (Moore et al. 1997). We give the correlation measurements of the cluster members that are located within $1R_{vir}$ from the cluster center in Table 7. The parameters that correlate with each other are plotted in Fig. 11&12 and discussed in Sect. 6. The cases where the correlation coefficient is 0.5 or above, while the trend is difficult to see, are given in the Appendix, Fig. A.2.

Fig. 6. Histograms of the mean misalignment between kinematic and photometric major axes ($\Delta\phi$), mean $k_{3,5}/k_1$ and standard deviation of kinematic position angle (σ_{PA}). The local sample is given in Fig. (a),(b) and (c) in blue, shaded. Our sample is given in Fig. (d),(e) and (f): field galaxies in red, shaded and cluster galaxies in light yellow, not shaded. In Fig. (g),(h) and (i) we show the galaxies in our sample that have H_α luminosities in the same interval as the local sample. This subsample is presented using the same color-coding as our whole sample, but shaded differently: horizontal shading represents the cluster members and 45° shading represents the field galaxies. $\Delta\phi$ of the galaxies that have $\epsilon \leq 0.1$ (galaxy 1F2, 2F4, 2F11, 2F12 and 4C3 in “this sample”, NGC 628, NGC 3184, NGC 3938 and NGC 5713 in the local sample), $k_{3,5}$ of galaxy 1F5 (this sample) and all parameters for galaxy 1F10, 2F5, 2F11 and 2F15&16 (this sample) are doubtful as explained in Sect. 5.6. Therefore they are excluded from the histograms.

5.6. The Fraction of Irregular Gas Kinematics

We quantified irregularities in gas kinematics using three different parameters and for each of them, we compared the number distribution of field and cluster galaxies. Now we will look at the fraction of galaxies that have irregular gas kinematics. Fractions that are measured for each irregularity type separately and also without distinguishing between the three types are given in Table 10. We obtain very similar fractions of irregular gas kinematics for cluster and field environments. Each irregularity parameter gives a very different fraction compared to the others, which will be discussed in Sect. 6.

5.7. Special Cases

Here we explain the cases that we exclude from our analysis. For the same information on the MS 0451 sample, see Paper III, Sect. 4.1. For face-on galaxies, photometric position angle measurements are very uncertain. Since LOS velocities are very small in such cases, the effect of noise becomes more pronounced in velocity fields. This causes $\Delta\phi$ to be unreliable. Therefore we excluded such cases from our analysis (2F4, 2F11, 2F12, 4C3). Among those, 2F11 is an extreme case which is completely excluded from the analysis (see Fig.B.28.e). The other galaxies that we did not use in our analysis are 2F5,

2F15&16. 2F5 does not have any signal in the upper slit, which affects the measurements. Looking at the iso-velocity lines on the receding side (Fig.B.23.e), it looks as if the highest positive velocities are located in the top right corner, which is missing on the map. 2F15&16 (see Fig.B.33) are at the same redshift, however it is not clear what kind of objects they are and the emission line they have could not be identified. The velocity field includes information from both, but most of it comes from 2F15. The [OIII]5007 velocity field of 4F4 (see Fig.B.46.e) looks quite disturbed, although the flux map of the same emission line looks rather regular. Emission from this galaxy is very strong and therefore we can rely on its (ir)regularity parameters.

6. Discussion

6.1. Frequency Distribution

We analyze together gas kinematics and stellar photometry of spiral galaxies in clusters and in the field. We find that the fraction of galaxies that have irregular gas kinematics is very similar in our cluster and field samples. These two samples also give a very similar frequency distribution of each (ir)regularity parameter. When interpreting the results we have to consider that our sample selection is based on the emission line flux of galaxies. A comparison of our sample with a local sample from SINGS

Table 5. Parameters quantifying the (ir)regularity of the gas kinematics measured for our sample.

Column (1): object ID; Col. (2): maximum radius for which the kinematic parameters could be calculated. The conversion from arcsecond into kpc was done as explained in Wright (2006); Col. (3): standard deviation of the kinematic position angle (σ_{PA}); Col. (4): mean misalignment between the kinematic and photometric position angles ($\Delta\phi$); Col. (5): mean $k_{3,5}/k_1$ of the analysis done while fixing the position angle and the ellipticity to their global values; Col. (6): V_{asym} parameter of Shapiro et al. (2008) measured as described in Sect. 6. The error is the standard deviation of the parameter in the range of observations.

For 1F11 and 2F15&16, the spectroscopic redshifts are not available. Therefore we give R_{\max} of these objects in arcseconds. $k_{3,5}/k_1$ of galaxy 1F5, $\Delta\phi$ of the galaxies that have $\epsilon \leq 0.1$ (galaxy 1F2, galaxy 2F4, galaxy 2F12 and galaxy 4C3) and all parameters for galaxy 1F10, galaxy 2F5, galaxy 2F11 and 2F15&16 are rather meaningless as explained in Paper III for the MS 0451 sample and here, in Sect. 5.6 for the rest. Therefore they are excluded from the analysis.

Fig. 7. (Ir)regularity parameters versus each other. The regularity threshold of each parameter is shown with a dashed line. The galaxies in the local sample are used only for determination of the regularity thresholds as explained in Paper III. They are not used in correlation measurements. The galaxies that are excluded from the correlation as explained in Sect. 5.6 are indicated with their names on the plot. *Top*: standard deviation of the kinematic position angle (σ_{PA}) versus mean $k_{3,5}/k_1$. Data points that are far out of the general distribution are shown separately, on top of the main plot. *Middle*: standard deviation of kinematic position angle (σ_{PA}) versus mean misalignment between kinematic and photometric axes ($\Delta\phi$). *Bottom*: mean $k_{3,5}/k_1$ versus mean misalignment between kinematic and photometric axes ($\Delta\phi$). Data points that are far out of the general distribution are shown separately, on the right side of the main plot.

shows that some galaxies in both our cluster and field samples have higher H_α luminosities, and therefore higher star formation rates (Fig.1). In some of these cases, high star formation activity might be the result of some type of interaction. But it does not seem to be the general case, since we find no correlation between the H_α luminosity and the irregularity in gas kinematics

Table 6. K-S statistics of (ir)regularity parameters of the cluster and field galaxies in our sample.

| | D | P |
|----------------------|------|------|
| σ_{PA} | 0.18 | 0.87 |
| $k_{3.5}/k_1$ | 0.18 | 0.86 |
| $\Delta\phi$ | 0.32 | 0.21 |

D: K-S statistics specifying the maximum deviation between the cumulative distribution of the given parameter for cluster and field galaxies in our sample; P: significance level of the K-S statistics.

Note: $k_{3.5}/k_1$ of galaxy 1F5, $\Delta\phi$ of the galaxies that have $\epsilon \leq 0.1$ (galaxy 1F2, galaxy 2F4, galaxy 2F12 and galaxy 4C3) and all parameters for galaxy 1F10, galaxy 2F5, galaxy 2F11 and 2F15&16 are excluded from the calculations as explained in Sect. 5.6.

$\Delta\phi$ of the galaxies that have $\epsilon \leq 0.1$ (galaxy 1F2, galaxy 2F4, galaxy 2F12 and galaxy 4C3 in “this sample”, NGC 628, NGC 3184, NGC 3938 and NGC 5713 in the local sample), $k_{3.5}/k_1$ of galaxy 1F5 (this sample) and all parameters for galaxy 1F10, galaxy 2F5, galaxy 2F11 and 2F15&16 (this sample) are doubtful as explained in Paper III. Therefore they are excluded while calculating the correlation coefficients. For the calculation of the correlations with the redshift, only field galaxies were used. So the results do not have the bias of the environment.

(see Table 7). It has to be considered, however, that $H\alpha$ luminosity of a galaxy can also increase due to facts that are unrelated to interactions such as regular starbursts (Kennicutt 1998).

In Fig. 6 (g), (h) and (i) we show how the subsample of galaxies that have $H\alpha$ luminosities within the same interval as the SINGS sample is distributed in the (ir)regularity parameters

Table 8. $H\alpha$ luminosities.

Column (1): galaxy ID; Col. (2): $H\alpha$ luminosity; Col. (3): emission line that is used for calculating the $H\alpha$ luminosity.

The errors in $H\alpha$ luminosities are estimated to be $\sim 50\%$ based on the width of the histograms in Fig. 5.

Fig. 8. (Ir)regularity parameters versus R/R_{vir} . The regularity threshold of each parameter is shown with a dashed line. # symbol indicates the galaxies that are not used in correlation measurements. 4C2 is excluded because the correlations are measured inside $1 R_{\text{vir}}$. 4C3 is excluded from the correlation measurement of $\Delta\phi$ since it has $\epsilon \leq 0.1$ (See Sect. 5.6). *Top:* mean $k_{3,5}/k_1$ versus R/R_{vir} . *Middle:* mean misalignment between kinematic and photometric axes ($\Delta\phi$) versus R/R_{vir} . *Bottom:* standard deviation of kinematic position angle (σ_{PA}) versus R/R_{vir} .

space. The field galaxies that are populating the high irregularity end of the plots are not necessarily the ones with high H_α luminosities. So, independent from whether the high star formation galaxies are included or not, the distribution of cluster and field galaxies in irregularity space is very similar. The majority of the field galaxies in our sample are more irregular than local field galaxies according to at least one of the three (ir)regularity criteria. This is the case even if we take into account only the ones that have H_α luminosities within the same interval as the

Fig. 9. Rest frame B-V color versus the mean misalignment between the photometric and the kinematic major axes ($\Delta\phi$). The line indicates the correlation. The galaxies in the local sample are not used in the correlation measurement, but they are shown in the plot for comparison. The galaxies that are excluded from the correlation as explained in Sect. 5.6 are indicated with their names on the plot.

Table 9. K-S statistics comparing the kinematic (ir)regularity parameters of the galaxies in our sample classified as spirals or irregulars using their photometry.

| | D | P |
|----------------------|------|------|
| σ_{PA} | 0.15 | 0.99 |
| $k_{3,5}/k_1$ | 0.10 | 1.00 |
| $\Delta\phi$ | 0.25 | 0.79 |

D: K-S statistics specifying the maximum deviation between the cumulative distribution of the given parameter for spiral and irregular galaxies in our sample; P: significance level of the K-S statistics.

Note: $k_{3,5}/k_1$ of galaxy 1F5, $\Delta\phi$ of the galaxies that have $\epsilon \leq 0.1$ (1F2, 2F4, 2F12 and 4C3) and all parameters for 1F10, 2F5, 2F11 and 2F15&16 have been excluded from the calculations as explained in Sect. 5.6.

Table 10. Irregularity fraction.

| | frac $_{\sigma_{\text{PA}}}$ | frac $_{\Delta\phi}$ | frac $_{k_{3,5}/k_1}$ | frac $_{\text{any}}$ | frac $_{\text{all}}$ |
|-----------------|------------------------------|----------------------|-----------------------|----------------------|----------------------|
| | (1) | (2) | (3) | (4) | (5) |
| field & cluster | $11 \pm 5 \%$ | $68 \pm 7 \%$ | $32 \pm 7 \%$ | $80 \pm 6 \%$ | $4 \pm 3 \%$ |
| only field | $10 \pm 6 \%$ | $65 \pm 9 \%$ | $32 \pm 9 \%$ | $76 \pm 8 \%$ | $3 \pm 3 \%$ |
| only cluster | $13 \pm 8 \%$ | $73 \pm 11 \%$ | $31 \pm 12 \%$ | $88 \pm 8 \%$ | $6 \pm 6 \%$ |

Column (1): fraction of irregular velocity fields according to σ_{PA} criterion; Col. (2): fraction of irregular velocity fields according to $\Delta\phi$ criterion; Col. (3): fraction of irregular velocity fields according to $k_{3,5}/k_1$ criterion; Col. (4): fraction of irregular velocity fields according to at least one of the three criteria; Col. (5): fraction of irregular velocity fields according to all the three criteria together.

Poisson errors are given for each fraction.

Note: $k_{3,5}/k_1$ of galaxy 1F5, $\Delta\phi$ of the galaxies that have $\epsilon \leq 0.1$ (galaxy 1F2, galaxy 2F4, galaxy 2F11, galaxy 2F12 and galaxy 4C3) and all parameters for galaxy 1F10 have been excluded from the calculations as explained in Paper III.

SINGS sample, which are mostly in the interval $0.1 \leq z \leq 0.5$. This could be the result of a higher occurrence of disk building processes such as mergers and accretion events at these redshifts. Using N-body simulations, Gottlöber et al. (2001) investigate the relative major merger rate of the population of cluster, group and isolated halos as a function of redshift. They find that for cluster galaxies, the relative merger rate increases with redshift while it decreases for isolated galaxies. At $z \sim 0.5$, they find the major

merger rate in the field to be two times as high as that in clusters (see Gottlöber et al. 2001, Fig. 9).

6.2. The Fraction of Irregular Gas Kinematics

Yang et al. (2008) analyze the [OII] doublet velocity fields ($2'' \times 3''$ field of view) of 63 intermediate mass ($M_{\text{stellar}} \geq 1.5 \times 10^{10} M_{\odot}$) field galaxies at $z = 0.4 - 0.75$. They find that 26% of these galaxies have velocity fields and velocity dispersion maps that are both incompatible with disk rotation. Our results show that $10 \pm 9\%$ (according to σ_{PA}), $60 \pm 15\%$ ($\Delta\phi$), $30 \pm 14\%$ ($k_{3,5}/k_1$) of less massive galaxies at the same redshift interval have irregular gas kinematics. In our sample, 13 of 48 field and 6 of 30 cluster galaxies have intermediate masses while the rest are less massive (see Table B.1). Among those, there are 10 field galaxies that are within redshift interval $z = 0.40 - 0.75$ and only 4 have strong enough emission for the analysis of their gas kinematics (2F4, 3F8, 4F5 and 4F12). This number is too few to be able to make a comparison with the results of Yang et al. (2008).

It is known from the local Universe that most galaxies in the central parts of galaxy clusters lack gas. To be able to study velocity fields of galaxies, priority was given to emission line galaxies in our sample selection. Therefore, most cluster galaxies in our sample are perhaps just infalling and have not been severely affected by the cluster environment yet. This would explain the similarity between the gas kinematics of cluster and field galaxies in our sample.

We use $k_{3,5}/k_1$, σ_{PA} and $\Delta\phi$ to trace the effects of the interaction processes on gas kinematics. We find that the irregularity fractions measured using each of these parameters are very different from one another: σ_{PA} gives a value around 10%, $k_{3,5}/k_1 \sim 30\%$ and $\Delta\phi \sim 70\%$ for both cluster and field galaxies. This may have a number of different reasons. One is the effect of lower spatial resolution for intermediate redshift galaxies. Our simulations in Paper III, Appendix A, indicate that small scale irregularities may be smeared out as a result of the resolution effects. A misalignment between the stellar disk and the rotation plane of the gas on the other hand is unlikely to be affected much by low resolution. One should also realize that not all galaxies with high $\Delta\phi$ are irregular. For example, galaxies with bars can have larger $\Delta\phi$ values. Also, some galaxies in the local universe are found showing regular kinematics with an HI polar disk (perpendicular to the stellar disk) (van Gorkom & Schiminovich 1997; Stanonik et al. 2009). There are even merger remnants in the local universe that have very regular gas velocity fields such as NGC 3921 (Hibbard & van Gorkom 1996).

We check whether some of the field galaxies in our sample belong to pairs or groups. Our analysis shows that the galaxies, for which this might be the case, are not more irregular than the rest of the field sample. This information is important for studying the environmental dependence of irregularities in gas kinematics. The projected distances between some of our galaxies, which are at the same redshift, suggest that they may belong to a gravitationally bound system. These are: 2F3 and 2F4 (in 26 kpc distance from each other), 2F10 and 2F11 (262 kpc), 4F10 and 4F12 (737 kpc), 4F5, 4F6 and 4F7 (4F5-4F6 842 kpc, 4F6-4F7: 775 kpc, 4F5-4F7: 1.17 Mpc). The average values of each irregularity parameter for these galaxies, excluding the unreliable values that are mentioned in Sect. 5.6 are $k_{3,5}/k_1 = 0.15$, $\sigma_{\text{PA}} = 13$ and $\Delta\phi = 19$.

6.3. Correlations With Photometric Parameters

The anti-correlation we find between the rest frame B-V color and $\Delta\phi$ shows that galaxies which have more irregular gas kinematics have higher star formation rates. This correlation is valid for cluster members and field galaxies together and also cluster members alone, although there are some galaxies that show a large deviation from this correlation (see Fig.9). The high star formation activity and irregular gas kinematics of the galaxies that are located in the upper-left part of the plot are most probably caused by interaction mechanisms. Galaxy-galaxy interactions in the field are known to induce starbursts. According to models, it is claimed that most interaction processes in clusters increase star formation activity at the beginning before they eventually suppress it: Gravitational interactions are expected first to trigger nuclear gas infall. Models by Fujita (1998) show that increased star formation activity is expected in case of harassment, since high-speed encounters between galaxies cause gas to accumulate to centers of galaxies. Ram-pressure stripping, which is the hydrodynamic interaction between the hot ICM and the cold ISM, leads to an increase of the external pressure, shock formation, thermal instabilities and turbulent motions within the disk. Evrard (1991) and Bekki & Couch (2003), for example, show that all these events increase cloud-cloud collisions and cloud collapse, and therefore enhance star formation activity. However, in case of ram-pressure stripping, there are not many observations supporting this picture. One example that experiences ram-pressure stripping is CGCG 97-023 in A1367, where enhanced star formation activity per unit mass, compared to galaxies of similar type and luminosity is confirmed (Gavazzi et al. 1995). Models of Fujita (1998) and Fujita & Nagashima (1999) that quantify the variations of the star formation activity, show that on short timescales ($\sim 10^8$ yr) in high-density, rich clusters, the star formation activity can increase by up to a factor of 2 at most. But on longer timescales, removal of the HI gas leads to a decrease of the fuel feeding the star formation, and galaxies become quiescent (Fujita 1998; Fujita & Nagashima 1999; Okamoto & Nagashima 2001).

We find for our cluster sample that $\Delta\phi$ becomes smaller with increasing stellar mass (Fig.12). This anti-correlation shows that galaxies with more massive stellar disks have more regular gas kinematics. Galaxies that have very irregular gas kinematics all have less massive stellar disks. This correlation could mean that the more massive a stellar plane is, the more difficult it becomes to perturb the gas in it. Also perturbed gas settles into the disk more quickly in case the galaxy has a massive stellar disk.

We find that M_{20} correlates with $\Delta\phi$ for cluster members. M_{20} becomes very large in case the galaxy light has a clumpy distribution. Since clumpiness is mainly caused by star forming regions, it means that galaxies that have irregular gas kinematics have more star formation. M_{20} also increases towards later types. Since galaxies that have high mass concentration (earlier types) are more resistant to tidal mechanisms, the correlation we find is expected as a result of this fact as well. The concentration parameter on the other hand, which is another indicator of galaxy type, does not give any correlation with the irregularity in gas kinematics. Therefore the substructures must be the main cause of the correlation that we find.

We find that two different indicators of star formation (M_{20} and B-V) correlate with irregularity in the gas kinematics and this relation is consistent with the results of simulations. Both correlations are found with the $\Delta\phi$ parameter, which shows that $\Delta\phi$ is a good indicator of interaction processes. We need to note that $\Delta\phi$ cannot be considered as a pure indicator of interactions

Fig. 10. Histograms of the mean misalignment between the kinematic and photometric major axes ($\Delta\phi$), the mean $k_{3,5}/k_1$ and the standard deviation of the kinematic position angle (σ_{PA}). Spiral galaxies in our sample are given in blue (shaded), irregular galaxies in red (not shaded) and spiral galaxies in the local sample are given in light yellow, shaded), irregular galaxies in the local sample in black (not shaded). $\Delta\phi$ of the galaxies that have $\epsilon \leq 0.1$ (galaxy 1F2, 2F4, 2F12 and 4C3 in “this sample”, NGC 628, NGC 3184, NGC 3938 and NGC 5713 in the local sample), $k_{3,5}$ of galaxy 1F5 (this sample) and all parameters for galaxy 1F10, 2F5, 2F11 and 2F15&16 (this sample) are doubtful as explained in Sect. 5.6. Therefore they are excluded from the histograms.

since it is sensitive to bars that are misaligned with the disk. Even though the formation of a bar can be triggered by environmentally induced gravitational instabilities such as tidal interactions between galaxies and the cluster potential well, it can also just be the result of a misalignment between the disk and the triaxial halo of the galaxy itself (Kodama & Smail 2001; Bekki & Freeman 2002). Since a bar is not necessarily formed by an interaction process, we remeasured the correlation of $\Delta\phi$ with the other parameters excluding the cases where we see that a bar has an important contribution to the $\Delta\phi$ value (3F7, 1F6 and 2C3). The results remained the same.

We find a correlation between the disk scale length and σ_{PA} (Fig. 11a). However, what we see on the plot is an increasing deviation of σ_{PA} values with increasing R_d rather than a correlation. While small galaxies are all regular, there are both regular and irregular cases among larger galaxies. It is known that some interaction processes are more effective on larger galaxies such as interactions between galaxies and the cluster potential well, viscous stripping and thermal evaporation. Tidal interactions between galaxies, on the other hand, are more efficient on smaller galaxies (Byrd & Valtonen 1990). What we see in our data might be an indication of the activity of some of the first group processes in the central $1R_{vir}$ of the clusters in our sample.

We find that M_B and σ_{PA} anti-correlate with each other (Fig. 11b) showing that more massive galaxies have more irregular gas kinematics. Since larger galaxies are also more massive (Trujillo et al. 2004), the interpretation of this correlation is the same as the correlation that we find for the disk scale length: one or a combination of the following mechanisms might be effective on the cluster members in our sample: viscous stripping, thermal evaporation and tidal interactions between galaxies and the cluster potential well.

For the correlations that we find for cluster galaxies, where the σ_{PA} parameter is involved, it should be considered that there are only two galaxies that are slightly above the irregularity threshold of σ_{PA} (Fig. 11a&b). Therefore, although we discuss

the possibility of these correlations being a result of cluster specific interaction mechanisms, this is not a strong result. Also the anti-correlation we find between the stellar mass and $\Delta\phi$ (Fig. 12) is in contradiction with these correlations. This can also be explained if the causes of $\Delta\phi$ are different from those causing σ_{PA} . This is clear from the fact that many more galaxies have high $\Delta\phi$.

6.4. Comparison With High Redshift Studies

Shapiro et al. (2008) use a method that is based on kinemetry to distinguish merging and non-merging systems. They quantify the asymmetries in both the velocity field and the velocity dispersion map of ionized gas. Using the measurements of these two parameters for template galaxies, they determine where merging and non-merging systems are located on the plane of these parameters versus each other and define a criterion to distinguish them from one another: $K_{asym} = \sqrt{V_{asym}^2 + \sigma_{asym}^2} = 0.5$. We measured the V_{asym} parameter of our velocity fields (Table 5) and compared these with the V_{asym} of the merging and non-merging galaxies and models in Shapiro et al. (2008) (See Fig. 13). The quality of our sigma-maps is not satisfactory for an analysis. However, the possibility that σ_{asym} and V_{asym} give contradictory results is very low (see Shapiro et al. 2008, Fig. 5). Therefore, we use V_{asym} alone with the purpose of making a comparison between the methods. To measure a global ellipticity and a global inclination, which are used while measuring the V_{asym} parameter, we calculate the median of their values outside half the full width at half maximum of the seeing.

If we look at the V_{asym} distribution of our galaxies, we see that most of them are located in the region of the non-merging galaxies, as defined by Shapiro et al. (2008) (Fig. 13a,b). V_{asym} is similar to $k_{3,5}/k_1$ and a comparison between these parameters for our galaxies shows that they correlate with each other (Fig. 14, correlation coefficient=0.86). On the other hand, the

Fig. 11. (Ir)regularity parameters versus some photometric quantities. For each plot, the line shows the correlation between the given parameters. The local galaxies are not used in correlation measurements, but shown as a reference in each plot. The names that are written in red and italic belong to the galaxies that are excluded from the correlation as explained in Sect. 5.6. *a*: The disk scale length (R_d) versus the standard deviation of the kinematic position angle (σ_{PA}). The standard deviation of σ_{PA} is measured within bins that are indicated with horizontal error bars and the mean σ_{PA} in each bin is given with a rectangular green symbol while the deviation from the mean is given with vertical error bars. *b*: Absolute magnitude in the B band (M_B) versus the standard deviation of the kinematic position angle (σ_{PA}). *c*: Rest-frame ($B-V$) color versus the mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). *d*: M_{20} index versus the mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). The thick green line shows the correlation obtained excluding the cases where the $\Delta\phi$ value mainly indicates a clumpy light distribution or a bar instead of an abnormality in the position of the kinematic axis. The galaxies for which this is the case are indicated with # symbol next to them. Measuring the correlation after excluding these galaxies gives the same result.

Fig. 12. $\Delta\phi$ versus stellar mass. The names that are indicated belong to the galaxies that are excluded from the correlations as explained in Sect. 5.6. The line shows the correlation that is measured using cluster galaxies only.

classification thresholds are quite different for the two criteria.

Following Shapiro et al. (2008), most of our objects would be regular while many more galaxies are classified as irregular with our method. This is visible in Fig. 13 where the V_{asym} distribution of our galaxies is given together with non-mergers and mergers in Shapiro et al. (2008). Classification of these galaxies according to the $k_{3,5}/k_1$ criterion is indicated on the same plot. While the method of Shapiro et al. (2008) aims at separating mergers from non-mergers, it would not fulfill our requirement of tracing the imprints of environmental processes. 4F7 (in the non-merger region with $V_{asym}=0.17$) is a good example to explain that since the deviation of the position angle, the residual map of the velocity field and the simple rotating disk model and also the galaxy image itself provide signs of a merger.

We find that the $z \sim 2$ galaxies in Shapiro et al. (2008) are more irregular than our complete sample that includes both cluster and field galaxies in $0.10 \leq z \leq 0.91$ (see Fig. 13b and c). The K-S test results show that the maximum deviation between these two distributions is 59% and the probability that the samples are similar is 0.002.

Another anti-correlation we find is between the stellar mass and $\Delta\phi$ of cluster galaxies. It shows that galaxies with more massive stellar disks have more regular gas kinematics. This correlation could mean that the more massive a stellar plane is, the more difficult it becomes to perturb the gas in it. Also perturbed gas settles into the disk more quickly in case the galaxy has a massive stellar disk.

To compare our fraction of galaxies that have irregular gas kinematics with that of Shapiro et al. (2008) at $z \sim 2$ we measure for the galaxies in our sample the V_{asym} parameter, which is defined by Shapiro et al. (2008) to distinguish merging and non merging systems. Comparison of our sample, that includes both field and cluster galaxies within $0.10 \leq z \leq 0.91$ with their SINS sample shows that $z \sim 2$ galaxies are more irregular than the galaxies we analyze in this paper (see Fig. 13b and c).

Acknowledgements. We would like to thank Daniel Kelson for making his sky subtraction algorithm public, and Scott Trager for his help in using it. We thank Davor Krajinović for the Kinemetry software. We are grateful to the authors of Daigle et al. (2006) for kindly providing us with the H α velocity fields of the galaxies in the SINGS local sample. We thank Jacqueline van Gorkom for fruitful discussions. We appreciate the efficient support of ESO and the Paranal staff. This work has been financially supported by the *Volkswagen Foundation* (I/76 520), the *Deutsche Forschungsgemeinschaft, DFG* (project number ZI 663/6) within the Priority Program 1177, the Kapteyn Astronomical Institute of the University of Groningen and the German Space Agency *DLR* (project number 50 OR 0602). EK thanks the Netherlands organization for international cooperation in higher education for the Huygens grant. This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

**Appendix A: Relations between kinematic
(ir)regularity parameters and photometric
quantities**

Fig. A.1. (Ir)regularity parameters versus some photometric quantities and redshift. Although the correlation coefficient is above 0.4 in each of these cases, the trend is difficult to see. Therefore we show the plots here, but do not discuss them further in Sect. 5 and 6. The local galaxies are shown as a reference in each plot, but used in correlation measurements of the redshift only. Galaxies that are excluded from the correlations as explained in Sect. 5.6 are indicated on the plots with their names in black. **a)** M_{20} index versus the mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). The correlation is given with the black thin line. The thick red line shows the correlation obtained excluding some additional cases where the $\Delta\phi$ mainly indicates the clumpy light distribution (1C7, 2C5, 4C2, 3F8, 4F5 and 4F6) or a bar (2C3, 1F6 and 3F7) instead of an abnormality in the position of the kinematic axis. These galaxies are indicated with their names in red, italic letters. The correlation coefficient of the black line is 0.4 and it increases slightly to 0.45 when the mentioned galaxies are excluded. **b)** Redshift versus the mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). The correlation is measured for our sample and the SINGS sample together. To be able to investigate the relation independently from environmental effects, cluster members are excluded from the measurement. In case of the local sample, galaxy names that are written on the plot belong to field galaxies that have doubtful $\Delta\phi$ values and to cluster members. For our sample, since cluster galaxies are shown with different symbols, the names are used for indicating the field galaxies that are excluded from the correlation only. The correlation coefficient we find is 0.7. An important question is whether the local galaxies from SINGS and our galaxies can be treated as a homogenous sample in this exercise. As discussed in Sect. 6, they have different star formation properties caused by the differences in the sample selection criteria of the two. The correlation excluding the galaxies in our sample that are outside the $L_{H\alpha}$ interval of the local galaxies gives a coefficient of 0.84. Including in the correlation the cluster members that are in the same $L_{H\alpha}$ interval as the local galaxies gives 0.74. **c)** Rest-frame (V-I) color versus mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). **d)** Disk scale length (R_d) versus mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). **e)** Absolute magnitude in the B band (M_B) versus mean $k_{3.5}/k_1$. Data points that are far out of the general distribution are shown separately, on top of the main plot. **f)** Rest-frame (R-I) color versus mean misalignment between the photometric and kinematic major axes ($\Delta\phi$).

Fig. A.2. (Ir)regularity parameters versus some photometric quantities for cluster members only. Although the correlation coefficient is above 0.4 in each of these cases, there is no visible trend. Therefore we show the plots here, but do not discuss them further in Sect. 5 and 6. The local galaxies are not used in correlation measurements, but shown as a reference in each plot. Galaxies that are excluded from the correlations as explained in Sect. 5.6 are indicated on the plots with their names in red italic letters. **a)** The disk scale length (R_d) versus the mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). This is most probably spurious since it also is in contradiction with the correlation we find between M_s and $\Delta\phi$. **b)** The asymmetry parameter (A) versus the mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). **c)** Rest-frame ($V-I$) color versus the mean misalignment between the photometric and kinematic major axes ($\Delta\phi$). **d)** Rest-frame ($R-I$) color versus the mean misalignment between the photometric and kinematic major axes ($\Delta\phi$).

Appendix B: Individual galaxies

Here we present some figures showing the data and its analysis for each object in our sample. The HST image and the velocity field of each galaxy have the same orientation (the slit position is parallel to the x -axis). The velocities and the positions are given with respect to the continuum center of the galaxies.

B.1. Cluster galaxies

Fig. B.3. a) HST-ACS image of the galaxy in the V band. b) Rotation curves of different emission lines extracted along the central slit. c) H α velocity field. d) Normalized H α flux map.

Fig. B.4. a) HST-ACS image of the galaxy in the V band. b) Rotation curves of different emission lines extracted along the central slit. c) H β velocity field. d) Normalized H β flux map.

Fig. B.1. **a)** HST-ACS image of the galaxy in the V band. **b)** Rotation curves of different emission lines extracted along the central slit. **c)** Position angles of kinematic and photometric axes as a function of radius. **d)** Rotation curves extracted along the central slit and the kinematic major axis. **e)** H β velocity field. **f)** Velocity map reconstructed using 6 harmonic terms. **g)** Residual of the velocity map and the reconstructed map. **h)** Normalized H β flux map. **i)** Simple rotation map constructed for position angle and ellipticity fixed to their global values. **j)** Residual of the velocity map and the simple rotation map. **k)** Position angle and flattening as a function of radius. **l)** k_3/k_1 and k_5/k_1 (from the analysis where position angle and ellipticity are fixed to their global values) as a function of radius.

Fig. B.5. **a)** HST-ACS image of the galaxy in the V band. **b)** Rotation curves of different emission lines extracted along the central slit.

Fig. B.2. **a)** HST-ACS image of the galaxy in the V band. **b)** Rotation curves of different emission lines extracted along the central slit. **c)** Position angles of kinematic and photometric axes as a function of radius. **d)** Rotation curves extracted along the central slit and the kinematic major axis. **e)** $H\beta$ velocity field. **f)** Velocity map reconstructed using 6 harmonic terms. **g)** Residual of the velocity map and the reconstructed map. **h)** Normalized $H\beta$ flux map. **i)** Simple rotation map constructed for position angle and ellipticity fixed to their global values. **j)** Residual of the velocity map and the simple rotation map. **k)** Position angle and flattening as a function of radius. **l)** k_3/k_1 and k_5/k_1 (from the analysis where position angle and ellipticity are fixed to their global values) as a function of radius.

Fig. B.6. a) HST-ACS image of the galaxy in the V band. b) Rotation curves of different emission lines extracted along the central slit. c) Position angles of kinematic and photometric axes as a function of radius. d) Rotation curves extracted along the central slit and the kinematic major axis. e) [OII]3727 velocity field. f) Velocity map reconstructed using 6 harmonic terms. g) Residual of the velocity map and the reconstructed map. h) Normalized [OII]3727 flux map. i) Simple rotation map constructed for position angle and ellipticity fixed to their global values. j) Residual of the velocity map and the simple rotation map. k) Position angle and flattening as a function of radius. l) k_3/k_1 and k_5/k_1 (from the analysis where position angle and ellipticity are fixed to their global values) as a function of radius.

Fig. B.18. a.1) HST-ACS image of the galaxy in the V band. **a.2)** This cluster galaxy does not have emission lines. The spectra include an emission line from the galaxy below the target that is seen in the HST image. The redshift of this galaxy could not be determined from the composite spectrum. **a.3)** FORS2 image of the galaxies. Parallel lines represent the bottom slit which gives a composite spectrum of both galaxies together. **b)** Rotation curve of the galaxy that is below the target. It is obtained from the slit positioned inbetween the two galaxies (see a.3). Velocities were measured with respect to the velocity at the continuum center of the bottom slit. Signal level in the other two slits was not high enough to obtain a rotation curve.

Fig. B.15. **a)** HST-ACS image of the galaxy in the V band. **b)** Rotation curves of different emission lines extracted along the central slit. **c)** Position angles of kinematic and photometric axes as a function of radius. **d)** Rotation curves extracted along the central slit and the kinematic major axis. **e)** [OIII]5007 velocity field. **f)** Velocity map reconstructed using 6 harmonic terms. **g)** Residual of the velocity map and the reconstructed map. **h)** Normalized [OIII]5007 flux map. **i)** Simple rotation map constructed for position angle and ellipticity fixed to their global values. **j)** Residual of the velocity map and the simple rotation map. **k)** Position angle and flattening as a function of radius. **l)** k_3/k_1 and k_5/k_1 (from the analysis where position angle and ellipticity are fixed to their global values) as a function of radius.

Fig. B.52. a) HST-ACS image of the galaxy in the V band. b) Rotation curves of different emission lines extracted along the central slit.

Fig. B.55. a) HST-ACS image of the galaxy in the V band. e) Velocity field constructed using the emission line which could not be identified. h) Normalized flux map of the emission line which could not be identified.

Fig. B.53. **a)** HST-ACS image of the galaxy in the V band. **b)** Rotation curves of different emission lines extracted along the central slit. **c)** Position angles of kinematic and photometric axes as a function of radius. **d)** Rotation curves extracted along the central slit and the kinematic major axis. **e)** [OII]3727 velocity field. **f)** Velocity map reconstructed using 6 harmonic terms. **g)** Residual of the velocity map and the reconstructed map. **h)** Normalized [OII]3727 flux map. **i)** Simple rotation map constructed for position angle and ellipticity fixed to their global values. **j)** Residual of the velocity map and the simple rotation map. **k)** Position angle and flattening as a function of radius. **l)** k_3/k_1 and k_5/k_1 (from the analysis where position angle and ellipticity are fixed to their global values) as a function of radius.

Fig. B.54. **a)** HST-ACS image of the galaxy in the V band. **b)** Rotation curves of different emission lines extracted along the central slit. **c)** Position angles of kinematic and photometric axes as a function of radius. **d)** Rotation curves extracted along the central slit and the kinematic major axis. **e)** [OIII]5007 velocity field. **f)** Velocity map reconstructed using 6 harmonic terms. **g)** Residual of the velocity map and the reconstructed map. **h)** Normalized [OIII]5007 flux map. **i)** Simple rotation map constructed for position angle and ellipticity fixed to their global values. **j)** Residual of the velocity map and the simple rotation map. **k)** Position angle and flattening as a function of radius. **l)** k_3/k_1 and k_5/k_1 (from the analysis where position angle and ellipticity are fixed to their global values) as a function of radius.

Fig. B.56. V band HST-ACS image of galaxies that have very weak or no emission.

Table B.1. Photometric parameters for the whole sample.

| ID | α | δ | M_B | $B - V$ | $V - R$ | $R - I$ | $M_{stellar}[M_{\odot}]$ | A | C | G | M_{20} |

Column (1): object ID; Cols. (2, 3): RA and Dec (J2000); Col. (4): rest frame, galactic-extinction corrected Johnson- B magnitudes (k -correction applied using the `kcorrect` algorithm by Blanton & Roweis (2007)); Cols. (5–7): galactic extinction and k -corrected $B - V$, $V - R$ and $R - I$ colors measured from the FORS2/VLT images (The FORS2 filters B, V and I are close approximations to the Bessel (Bessell 1990) photometric system while R filter is a special filter for FORS2); Col. (8): Stellar mass (measured using the `kcorrect` algorithm by Blanton & Roweis (2007)); Col. (9): asymmetry index; Col. (10): concentration index; Col. (11): Gini coefficient; Col. (12): M_{20} index.

Table B.2. Morphological parameters for the MS 1008, MS 2137 and CI 0413 samples.

Column (1): object ID; Col. (2): component; Col. (3): total magnitude; Col. (4): effective radius of the bulge/scale length of the disk; Col. (5): Sérsic index of the bulge profile; Col. (6): flattening; Col. (7): position angle of the disk measured from North through East.

The photometric zero point of the magnitude measurements is $Z_p^{F606W} = 26.398$. The parameters of 2F14 are unreliable since there is a diffraction spike on top of it. The HST image of 3F7 is incomplete and therefore its parameters are also unreliable. The disk scale length of these galaxies is not used in the analysis. 3F13 could not be analyzed because of the diffraction spike on the image. Col. (4) is given in arcseconds in case the redshift of a galaxy is unknown.
